Web appendix A. Common method variance

A data collection at different time points reduces the potential threat of common method variance in our data set ex ante (Fuller et al. 2016). Additionally, we used an appropriate questionnaire design. First, the respondents were told that the study was anonymous and confidential and that there were no right or wrong answers. Moreover, the study started with the measures of the dependent variables (Chang et al. 2010). We calculated a single-factor test using confirmatory factor analysis. The results show that the models with all items loading on a single factor had a significantly worse fit than our proposed models did (see *Tab. A.1*).

Web appendix B. Endogeneity test

In order to reduce possible biases from endogeneity we used the instrumental variable (IV) approach. We checked whether the results of the studies change, if the exogenous variables are endogenized by including IVs for each marketing instrument. The IV's for study 1 are measured with one item: "The offline store is visually appealing; The physical store has a very good overall layout design; I believe that my personal data are well protected in this physical store; [Retailer] provides reliable service through its offline store; The physical store allows consumers to inform themselves about the online store; The employees are helpful when using the online store" (e. g., adapted from Montoya-Weiss et al. 2003; Oh et al. 2012). For study 2, we use brand attachment as an IV for online brand equity, which is theoretically a strong predictor for brand equity with one item ("I consider [retailer] as my first choice", e. g., Keller 2010; Park et al. 2010). Offline trust is used as an IV for online trust, as it was shown to be strongly associated with online trust ("[Retailer's] offline store can be trusted at all times", Bock et al. 2012). First, F-tests proved that the IVs are strong predictors of the analysed variables (see Tab. B.1). The IVs are included in the models to calculate consistent models in addition to the efficient (proposed) models (Antonakis et al. 2010, see Tab. B.2). Second, regarding the path estimates we verified whether changes emerged (Hausman 1978). Respective t-values were below the critical value of 1.96 and we conclude that the probability of endogeneity seems to be reduced.

	Model 1	Model 2

All items measured on 7-point Likert-type scales: 1 = strongly disagree, 7 = strongly agree.

Tab. C.1: Study 2: Reliability and validity (explorative)

Web appendix D. Study 2: Test for measurement invariance

We tested for measurement equivalence to ensure comparability across the three time points. First, we ensured configural invariance by estimating a baseline model in which the factor loadings and intercepts are freely estimated. Second, we tested for metric invariance by fixing the factor loadings of each item. A comparison of configural and the metric model shows that all deviations are within limits. We additionally relied on differences in the comparative fit indices (Chen 2007) to ensure measurement invariance. Partial metric invariance was ascertained by freely estimating some of the factor loadings.

Tab. D.1: Study 2: Measurement invariance across time points

Web appendix E. Study 2: Description of the cross-lagged model

Cross-lagged panel models are appropriate for studying causality in longitudinal data because reciprocal relationships between variables can be conceptualized over time (Allison et al. 2017). Autoregressive relationships between a variable and its prior state have to be modelled (Zyphur et al. 2019). The constructs are measured at three time points. We follow the advice of Burkholder and Harlow (2003) and include disturbance correlations in the cross-lagged design. These correlations were modelled between the same indicators across the three time points. Disturbance correlations are also included between all constructs at time point two and are then integrated at time point three. They are constrained and thus estimated equally (Allison et al. 2017).

Structural model fits: Model 1: CFI .837, TLI .830, RMSEA .091, SRMR .183, $\chi^2(1188) = 4863.598$, SCF = .89. Model 2: CFI .828, TLI .821; RMSEA .094, SRMR .184, $\chi^2(1188) = 5114.794$, SCF = .89. Notes: RPI = Repurchase intention, (1, 2, 3) = Time points, SCF = Scaling correction factor for MLM, N = 377. β = standardized coefficients. *** p < .001; ** p < .01; *p < .05; †p < .10; ns = not significant.

Tab. F.6: Study 2: Results of the alternative model (brand equity)
